1 Introduction

Recurrent Neural Networks (RNNs) are a class of artificial neural networks that are designed to process sequential data by capturing the temporal dependencies among the input elements. Unlike traditional feedforward neural networks, RNNs have feedback connections that allow information to be passed from one time step to the next. This unique architecture makes RNNs particularly useful for a wide range of tasks such as natural language processing, speech recognition, and time series analysis. The key advantage of RNNs is their ability to process variable-length sequences, making them highly adaptable to real-world applications. In this way, RNNs have become a powerful tool in the field of deep learning, and have opened up new avenues for research and innovation in the field of machine learning.

Long Short-Term Memory (LSTM) is a specialized type of Recurrent Neural Network (RNN) that was developed to address the vanishing and exploding gradient problems that commonly occur in traditional RNNs. Like RNNs, LSTMs are designed to process sequential data and have feedback connections that allow information to be passed from one time step to the next. However, LSTMs have a unique architecture that allows them to selectively remember or forget information over long periods of time. This is achieved through the use of specialized memory cells, which are connected by gates that control the flow of information into and out of the cells. The result is a network that is capable of processing sequential data with greater accuracy and efficiency than traditional RNNs.

For each timestep t , the activation $a^{<t>}$ and the output $y^{<t>}$ are expressed as follows:

$$a^{<t>} = g_1(W_{aa}a^{<t-1>} + W_{ax}x^{<t>} + b_a) \quad \text{and} \quad y^{<t>} = g_2(W_{ya}a^{<t>} + b_y)$$

2 Problem statement

The objective of this programming assignment was to deepen our understanding of the working of recurrent neural network (RNN) and its variant, long short-term memory (LSTM). The major task includes building a RNN for classification of sequential data.

Two of the dataset given for the tasks are as follows:

1. **Handwritten character dataset:** This dataset consists of subset of handwritten characters from Kan-nada/Telugu script.
2. **Consonant Vowel (CV) segment dataset:** This dataset consists of subset of CV segments from a conversational speech data spoken in Hindi language.

3 Methodology

We start by preprocessing the datasets for the given tasks. *Handwritten charecter dataset* sequence of consists of coordinates of 2-dimension that are generated while writing this charectors on a graphics tablet. We are required to feed these sequences to an **RNN** to classify the charecter to one of the classes. The sequences are min-max normalised in the range of $[0, 1]$, such that all the sequences are normalised and belong to the same input space. Figure 2 shows some samples from each classes after normalisation.

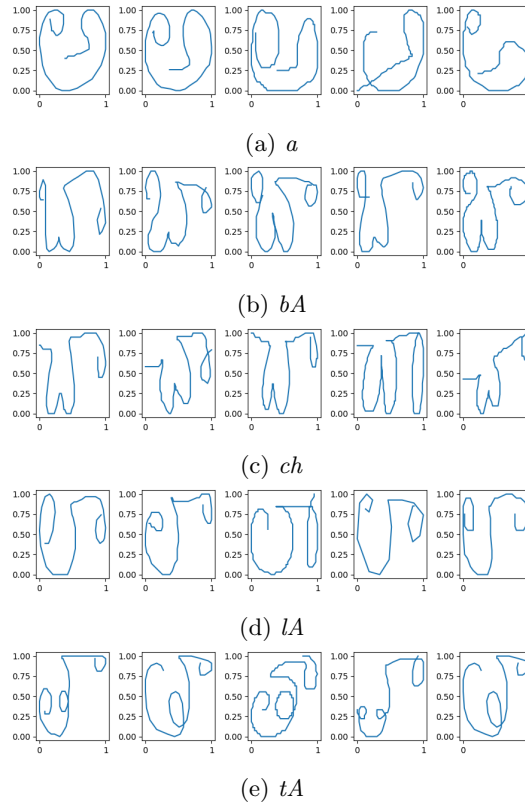

Figure 2: Normalised samples from the *Handwritten charecter dataset*

For the *CV dataset*, each sequence consists of vectors of 39-dimension. These vectors are MFCC(Mel frequency cepstral coefficient) features vector for every frame. We take the feature vectors as it is without any normalisation.

We considered a set of 6 architectures with different hyperparameters for each dataset, 3 of which are using RNNs and the rest using LSTMs. The summary of the architectures are given in Table 1 and 2.

Layer	Hidden unit	Activation function

Table 2: Architectures used on CV dataset

We use **Adam optimizers** for backpropagation with a learning rate of 0.0001. This was a decision we had to take due the loss oscillating more than we would like for the default larger learning rate. Stopping criteria for the training was kept as when the successive average epoch error difference falls below 10^{-4} .

For the last RNN and LSTM architectures for CV datasets, we used dropouts in the RNN layers to reduce overfitting of the models.

5 Observations

1. Sequence learning can be more difficult than learning from regular data due to challenges such as long-term dependencies, variable sequence length, time complexity, noisy or missing data, and interpreting model predictions.
2. When we work with data that has a time-based structure, such as text, speech or time-series data, it can be more difficult to understand the patterns and connections between events. Sequence models are important for tasks like understanding language, recognizing speech, and predicting future values in time series data.
3. RNNs and LSTMs can be computationally expensive to train, especially for complex architectures.
4. Using APIs for modeling RNNs are little tricky.
5. The loss function for RNN can saturate quickly due to the vanishing gradient problem, which occurs when the gradients become very small as they propagate backward through time. Techniques such as gating mechanisms help gradients propagate more effectively and avoid saturation.
6. LSTMs can be more effective than simple RNNs at capturing long-term dependencies in the sequence data, but they may require more computational resources.
7. Depending on the task, different LSTM architectures (such as stacked LSTMs) may perform better than others.
8. Overfitting can be a challenge when working with sequence datasets. Regularization techniques such as dropout or weight decay can help prevent overfitting.
